Abstract. Bounded Model Checking (BMC) is a popularly used strategy for program verification and it has been explored extensively over the past decade. Despite such a long history, BMC still faces scalability challenges as programs continue to grow larger and more complex. One approach that has proven to be effective in verifying large programs is called Counterexample Guided Abstraction Refinement (CE-GAR). In this work, we propose a complementary approach to CEGAR for bounded model checking of sequential programs: in contrast to CE-GAR, our algorithm gradually widens underapproximations of a program, guided by the proofs of unsatisfiability. We implemented our ideas in a tool called LEGION. We compare the performance of LEGION against that of CORRAL, a state-of-the-art verifier from Microsoft, that utilizes the CEGAR strategy. We conduct our experiments on 727 Windows and Linux device driver benchmarks. We find that LEGION is able to solve 12% more instances than CORRAL and that LEGION exhibits a complementary behavior to that of CORRAL. Motivated by this, we also build a portfolio verifier, LEGION<sup>+</sup>, that attempts to draw the best of LEGION and CORRAL. Our portfolio, LEGION<sup>+</sup>, solves 15% more benchmarks than CORRAL with similar computational resource constraints (i.e. each verifier in the portfolio is run with a time budget that is half of the time budget of CORRAL). Moreover, it is found to be  $2.9 \times$  faster than CORRAL on benchmarks that are solved by both CORRAL and LEGION<sup>+</sup>.

Keywords: Verification  $\cdot$  Bounded model checking  $\cdot$  Underapproximation widening.

#### 1 Introduction

Bounded Model Checking (BMC) [26,11,20,33] is a popular option for program verification, primarily due to its ability of side-stepping the necessity of synthesizing complex invariants. BMC harnesses the power of modern SMT solvers to verify a bounded set of behaviors of a program. The user, if interested, may

re-attempt verification with larger bounds once the program is proven correct with small bounds.

BMC operates by constructing a logical formula that symbolically captures all states reachable by a program under a user-provided bound. A *query*, referred to as the *verification condition (VC)*, is constructed as a conjunction of the program semantics and the negation of the property, which is also expressed as a logical formula. If the verification condition is satisfiable, it implies that some program execution violated the property of interest, thus the program is faulty. If unsatisfiable, the program satisfies the property, i.e. the program is safe under the chosen bound.

However, for large programs, BMC faces scalability challenges as the verification condition for the program tends to grow large, posing difficulties for the SMT solver. Prior work has answered this challenge by using the popular counterexample-guided abstraction refinement (CEGAR) strategy: start off with the VC for an abstraction of the program, and incrementally refine the abstraction until the program is decided as safe or faulty. The Stratified Inlining (SI) [26] algorithm is an instance of this strategy. SI starts off with an abstraction of only the entry procedure of the program, and then incrementally inlines callees, guided by counterexamples. Not surprisingly, the dynamic inlining strategy of SI has been found to be significantly more scalable than algorithms that statically inline all procedures [25]. The SI algorithm is used in practice by the CORRAL [24] verifier that powers Microsoft's Static Driver Verifier (SDV) [4].

In this work, we propose a new algorithm that uses proofs of unsatisfiability to widen underapproximate models of the program en route to verification of sequential programs. Our algorithm starts off by constructing a partial verification condition for only the program entry procedure and blocks all paths that invoke calls to procedures that have not yet been inlined. This constructs an underapproximation of the original program (because paths are blocked). A satisfiable result on an underapproximation will indicate the presence of a bug. If the VC is unsatisfiable, we examine its *proof of unsatisfiability* in order to guide the inlining of called procedures. The program can be declared safe when the proof of unsatisfiability does not depend on any procedure call that has not been inlined yet. We implemented our ideas in a tool called LEGION.

Further, we found that our underapproximation widening algorithm and the abstraction refinement strategy (used by CORRAL) demonstrate complementary behaviors—many programs that CORRAL struggles on, yield to the underapproximation based technique, and vice-versa. This observation motivated us to build a portfolio verifier, LEGION<sup>+</sup>, that runs both these techniques in parallel. We found that the portfolio is more effective than any of the tools alone (with similar computational resources, i.e. each verifier in the portfolio is run with a time budget that is half of the time budget of CORRAL). Both LEGION and LEGION<sup>+</sup> are available open-source at the *legion* branch of the *corral* repository<sup>4</sup>.

Our experiments are conducted on 727 Windows and Linux device driver benchmarks on which CORRAL struggles, i.e., CORRAL is unable to solve any of

<sup>&</sup>lt;sup>4</sup> https://github.com/boogie-org/corral.git (branch: legion)

these benchmarks in less than 200 seconds. We find that LEGION is able to solve 12% more instances than CORRAL with a time budget of 2 hours per instance. Further, the portfolio verifier, LEGION<sup>+</sup>, given half the time budget of CORRAL, solves 15% more benchmarks than CORRAL, and it is found to be  $2.9 \times$  faster than CORRAL on benchmarks that are solved by both CORRAL and LEGION<sup>+</sup>.

The primary contributions of this paper are as follows:

- We design a new algorithm, Underapproximation Widening guided Stratified Inlining, that uses proof-based artifacts to widen underapproximate models (in contrast to using counterexamples to refine overapproximate models).
- We implemented our ideas in a tool called LEGION for bounded program verification.
- We also design a portfolio verifier, LEGION<sup>+</sup>, that includes both overapproximation refinement and underapproximation widening to verify a program in an attempt to reap the benefits of both worlds.
- We evaluate both LEGION and LEGION<sup>+</sup> on a set of 727 programs from Windows Device Drivers [31] from the SDV test-suite and Linux Device Drivers from SVCOMP [7] benchmarks.

## 2 Background

This section presents background material that we use in the rest of the paper.

A logical formula consists of literals. A literal is either a variable or the negation of a variable. A logical formula expressed in a *Conjunctive Normal Formal* (CNF) is a *conjunction* of clauses where each clause is a *disjunction* of literals. Given a logical formula, a *satisfiability* solver returns whether the formula is *satisfiable* (SAT) or *unsatisfiable* (UNSAT). If a formula is SAT, the solver provides a model in the form of a satisfying assignment of the variables. If a formula is UNSAT, the solver returns an *unsatisfiable core* (unsat core), which is a subset of clauses of the input formula whose conjunction is still UNSAT.

#### 2.1 Language Model

We consider a programming language that represents a *passified* form of BOO-GIE programs [8]. A program consists of multiple procedures (*Proc*). We assume an *entry-point* procedure called **main** where program execution starts. Each procedure can have any number of local variable declarations followed by a series of basic blocks (*BasicBlock*). We assume that local variables are initially unconstrained. A basic block is labeled by a unique identifier and consists of multiple statements (*Stmt*) followed by a single control statement (*ControlStmt*). A control statement is either a *goto*, which takes a sequence of basic block labels and non-deterministically picks one to jump to, or a *return* that returns control back to the caller. Returning from **main** terminates the program execution. A statement is either an *assume* command or a procedure *call*. The statement (*assume*  $\varphi$ ) allows a feasible execution only if  $\varphi$  is satisfiable.

```
procedure foo1(int x, int y) {
procedure main() {
                                      L9: assume y == x + 1;
  int x, y, z; bool c;
                                          return; }
  L0: assume x == 0;
                                    procedure foo2(int x, int y) {
      assume y == 0;
      goto L1, L2;
                                      L10: assume y = x - 1;
  L1: assume c;
                                           return; }
      call foo(x, y);
      goto L3;
                                    procedure bar(int x, int y) {
  L2: assume !c;
                                      bool e;
      call bar(x, y);
                                      L11: goto L12, L13;
                                      L12: assume e;
      goto L3;
  L3: assume y != 0
                                            call bar1(x, y);
      return; }
                                           goto L14;
                                      L13: assume !e;
                                            call bar2(x, y);
procedure foo(int x, int y) {
  bool d;
                                           goto L14;
  L5: goto L6, L7;
                                      L14: return; }
  L6: assume d;
                                    procedure bar1(int x, int y) {
      call foo1(x, y);
                                      L15: assume y = x + 10;
      goto L8;
  L7: assume !d;
                                           return; }
      call foo2(x, y);
                                    procedure bar2(int x, int y) {
      goto L8;
  L8: return; \}
                                      L16: assume y = x - 10;
                                           return; }
```

Fig. 1: A Passified Program

We leave the set of variable types (Type) and expressions (Expr) unspecified. In practice, we can use any expression language that can be directly encoded in SMT. Our implementation uses linear arithmetic, fixed-size bit-vectors, uninterpreted functions, and extensional arrays. This combination is sufficient to realistically translate C programs into our language representation [24,21].

Note that the programs that we consider do not have global variables, return parameters of procedures, or assignments. These restrictions are without loss of generality [23]. Conversion of these additional feature into our language representation is readily available in tools like BOOGIE. A passified program makes it easy to describe the verification-condition generation process.

Given a program P, we consider the verification question of whether there exists a terminating execution of P. To be precise, we are interested in finding out whether there is any execution of main that reaches its *return* statement. If no such execution exists, then P is considered verified, or SAFE. Otherwise, we say that P is UNSAFE and return the execution trace with concrete variable values along the trace. Note that we consider a bounded version of the verification problem, i.e., we require that P does not contain any loops or recursive procedure

5

Fig. 2: Call graph of the program in Figure 1.

 $\begin{array}{l} \mathrm{pVC}(\texttt{main}):\\ & blk_{L0}\\ \wedge & (blk_{L0} \implies x == 0 \land y == 0\\ & \land ((blk_{L1} \land flow(0) == 1) \lor (blk_{L2} \land flow(0) == 2)))\\ \wedge & (blk_{L1} \implies c \land blk_{L3} \land flow(1) == 3)\\ \wedge & (blk_{L2} \implies \neg c \land blk_{L3} \land flow(2) == 3)\\ \wedge & (blk_{L3} \implies y \neq 0) \end{array}$ 

Fig. 3: Partial VC of main()

calls. All such loops and recursive calls must be unrolled to a pre-determined depth before proceeding with verification, and thus, the verification problem now becomes decidable (if the expression language of the program is decidable) [23].

#### 2.2 VC generation for a procedure

Consider a procedure **baz** that does not contain any procedure calls. This section outlines one way of verifying **baz**, i.e., finding out if it has a terminating execution. We use a process called Verification Condition (VC) generation on **baz** to construct a logical formula  $\Phi$  and feed it to an SMT solver. If  $\Phi$  is UNSAT, then the *return* statement in **baz** is unreachable and **baz** is SAFE. Otherwise, we extract the satisfiable model from the SMT solver, construct the execution trace and return UNSAFE along with the trace. We now outline the VC-generation process.

Suppose that **baz** takes input arguments  $\vec{x}$ . For each basic block j in **baz**, we define a boolean variable  $blk_j$  that is termed as the *control-flow* variable. Let  $st_j$  denote the conjunction of all assume statements in basic block j. Let successor(j) denote the targets of the *goto* statement in j, i.e., all the successor basic blocks in **baz**, to which control may jump non-deterministically from j. Let  $i_j$  be a unique integer constant representing basic block j. We also define an uninterpreted function  $flow : \mathbb{Z} \to \mathbb{Z}$  that records the non-deterministic choice

of the successor basic block of j. Given the above, we construct a logical formula  $\psi_j$  for each basic block j as follows:

$$blk_j \Rightarrow (st_j \land \bigvee_{s \in successor(j)} (blk_s \land (i_s == flow(i_j))))$$

If basic block j ends with a return statement instead of a goto, then  $\psi_j$  is:

$$blk_j \Rightarrow st_j$$

Assuming the first basic block of **baz**, where procedure execution begin, is labeled *s*, the VC of **baz** is constructed as follows:

$$blk_s \wedge \bigwedge_{l \in basicblocks(p)} \psi_l$$

In Figure 3, we show the VC of main of the program in Figure 1 as an example, where we ignore the procedure calls in main (i.e., treat them as (assume true)). We term such a VC (of a procedure where its calls are skipped) as the partial VC (pVC) of the procedure.

#### 2.3 Static versus Dynamic Inlining

Given a program P with a starting procedure main, one simple way to verify P would be to construct the VC of main by inlining all the procedure calls and check the satisfiability of VC(main) with an SMT solver. However, employing such a *static inlining* strategy can cause an exponential blowup in the size of the VC. Hence, we instead make use of *dynamic inlining* algorithm, called Stratified Inlining (SI) [26], that employs a Counterexample Guided Abstraction Refinement (CEGAR) technique [14] to *dynamically* inline procedure VCs. It has been shown that dynamic inlining scales better than static inlining [25]. Dynamic inlining produces more compact VCs during abstraction refinement which leads to significantly faster program verification.

#### 2.4 Verification with Stratified Inlining

The working of SI is shown in Algorithm 1. For the sake of simplicity, let us assume that each basic block in P may contain only a single procedure call. Every program point, from which a procedure is called, is termed as a callsite. For example, main in Figure 1, has two callsites; foo and bar which are called from basic blocks L1, L2 and L3 respectively. A static instance of a callsite is denoted with a pair (l, c) where l denotes the basic block identifier from which a call to the procedure c is made. A dynamic callsite is defined as a stack of static callsites which represents the runtime stack during a program's execution with main being present at the bottom of the stack. For example, the dynamic callsite corresponding to the call foo from L1 in main is given by [main, (L1, foo)]. The call graph of the program in Figure 1 is shown in Figure 2.

Proof-guided Underapproximation Widening for Bounded Model Checking

Algorithm 1: Stratified Inlining (SI) algorithm.

Innut, program D with starting proceeding main				
Input: program P with starting procedure main				
<b>Input:</b> An SMT solver $S$				
<b>Output:</b> SAFE, or UNSAFE $(\tau)$				
$1 \ C \leftarrow \{[\texttt{main}, s] \mid s \in callsites(\texttt{main})\}$				
2 $S$ .Assert(pVC(main, [main]))				
3 while true do				
4   $outcome \leftarrow OVERREFSTEP(P, C, S)$				
if $outcome == SAFE \lor outcome == UNSAFE(\tau)$ then				
6 <b>return</b> outcome				
7 else				
8   let NoDECISION( $_{-}, C'$ ) = outcome 9   $C \leftarrow C'$				
9 $C \leftarrow C'$				

The SI algorithm takes as input a program P with a starting procedure main and an SMT solver S. Initially, we add the dynamic callsites in main to a list C(Line 1) and then inline main, i.e., assert the pVC of main (Line 2). The callsites in C are termed as *open* callsites because they have not yet been inlined. The above steps construct an abstraction of P. The SI algorithm then iteratively calls the OVERREFSTEP routine on this abstraction (Line 4) to perform gradual refinement until we can reach a decision about whether P is SAFE or not. Each invocation of OVERREFSTEP can potentially inline more procedures by asserting their partial VC to the solver S. Thus, the state of the solver, as well as the set of open callsites C change across invocations of OVERREFSTEP. We discuss the *Overapproximation Refinement Guided Stratified Inlining (OverRefSI*) strategy used by the OVERREFSTEP routine in Section 2.5.

#### 2.5 Overapproximation Refinement Guided Stratified Inlining

The OVERREFSTEP routine given in Algorithm 2 demonstrates the inner workings of the *OverRefSI* strategy at each verification step. The *OverRefSI* strategy [26] for verifying a program works by iteratively firing overapproximation queries and gradually refining the abstraction of P. If the query returns UNSAT, then we can conclude that P is SAFE with respect to the given property. Otherwise, we extract all the open callsites that appear on the counterexample trace and refine the abstraction of P by inlining these callsites. If the counterexample trace trace contains no open callsites, then P is UNSAFE and we return the verdict along with the counterexample trace.

The OVERREFSTEP routine takes as input a program P, a set of open callsites C and an SMT solver S. The OVERREFSTEP routine is called iteratively in order to verify the safety of P. We demonstrate the working of *OverRefSI* to verify the pVC of main of Figure 1 in Table 1. At the beginning, the SI algorithm asserts the pVC of main to S and adds [main, (L1, foo)] and [main, (L2, bar)] to the list of open callsites C in step 0.

Algorithm 2: OVERREFSTEP(P, C, S)

**Input:** procedure P, set of callsites C, SMT solver S**Output:** SAFE, UNSAFE(*trace*), NODECISION( $\tau$ , C) 1 // Overapproximate check **2** if S.Check() == UNSAT then 3 return SAFE 4 else  $\tau \leftarrow \text{opencallsites}(\mathcal{S}.\text{Model}())$  $\mathbf{5}$ 6 if  $\tau == \emptyset$  then return UNSAFE(S.Model()) 7 8 else  $C' \leftarrow \emptyset$ 9 forall  $c \in \tau$  do  $\mathbf{10}$  $C' \leftarrow \text{INLINE}(\mathbf{P}, c)$ 11  $C \leftarrow (C - \tau) \cup C'$ 12return NoDecision $(\tau, C)$  $\mathbf{13}$ 

Next, the SI algorithm calls OVERREFSTEP with P, C and S as arguments. OVERREFSTEP fires an overapproximation query in Line 2. If the query is unsatisfiable, we return the SAFE verdict. If the query is satisfiable, we get the counterexample trace and extract all the open callsites on the trace in  $\tau$  (Line 5). If  $\tau$  is empty, i.e., the counterexample trace contains no open callsites, then the trace is not spurious and we can return an UNSAFE verdict with the trace (Line 7). Otherwise, we inline all the callsites in  $\tau$  and add all the new callsites that opened up due to the inlinings in C' (Line 11). Inlining a callsite c consists of asserting the partial VC of the procedure that was invoked from c.

Subsequently, the inlined callsites are removed from the list of open callsites C and new callsites that opened up due to the inlinings are added to C (Line 12). For example, in step 1 of Table 1, OVERREFSTEP fires an overapproximation query that returns SAT with a counterexample trace that contains the callsite of foo, i.e., [main, (L1,foo)]. This callsite is then inlined by asserting the pVC of foo to the solver. This opens up the callsites of foo1 and foo2. Since we have not been able to arrive at a decision regarding the safety of P at this step, a verdict of NODECISION is returned along with the list of inlined callsites  $\tau$  and the new list of open callsites C (Line 13).

Next, the SI algorithm calls OVERREFSTEP again and in step 2, it fires an overapproximation query again, which returns SAT with the counterexample trace containing the open callsite of foo1 that we inline by asserting the pVC of foo1. The verification process continues in this way by inlining the open callsites on the counterexample trace in every step, which gradually refines the pVC of main. Finally, in step 7, the overapproximation query returns UNSAT from which we can conclude that main is SAFE.

Step	Action	Open Callsites
0	Assert pVC(main)	[main, (L1,foo)]
		[main, (L2,bar)]
1	Overapprox check: SAT	
	Assert $pVC(foo)$	[main, (L2,bar)]
		[main, (L1, foo), (L6, foo1)]
		[main, (L1,foo), (L7, foo2)]
2	Overapprox check: SAT	
	Assert $pVC(foo1)$	[main, (L2,bar)]
		[main, (L1,foo), (L7, foo2)]
3	Overapprox check: SAT	
	Assert $pVC(foo2)$	[main, (L2, bar)]
4	Overapprox check: SAT	
	Assert $pVC(bar)$	[main, (L2,bar), (L12, bar1)]
		[main, (L2,bar), (L13, bar2)]
5	Overapprox check: SAT	
	Assert $pVC(bar1)$	[main, (L2,bar), (L13, bar2)]
6	Overapprox check: SAT	
	Assert $pVC(bar2)$	
7	Overapprox check: UNSAT	
	Return SAFE	

Table 1: Execution of *OverRefSI* on the program of Fig. 1

#### **3** Overview

#### 3.1 Underapproximation Widening

We propose a novel algorithm, Underapproximation Widening Guided Stratified Inlining (UnderWidenSI), that uses proofs of unsatisfiability to guide stratified inlining. UnderWidenSI maintains an underapproximated model of the target program and widens it until either the program is verified as safe or a bug is found.

We illustrate the UnderWidenSI strategy in Figures 4a to 4d. Assume that we are trying to verify whether some required property holds on a program. The space contained by the *yellow* ovals show the reachable program states while the *red* ovals depict error states on which the required property does not hold. The objective of a verification algorithm is to construct a *model* of the program that is precise enough to show that the program can reach an error state or prove that the error states are unreachable. Figures 4a to 4c show a safe program while Figure 4d depicts an unsafe program.

Consider Figure 4a: the *UnderWidenSI* algorithm starts off with the partial verification condition of the entry procedure and "blocks" executions though all its open callsites.

**Definition (Blocked callsites).** We use the term, *blocking* a callsite C, to imply that all paths that reach C are deemed infeasible. That is, blocking a callsite has the effect of replacing the callsite by (*assume false*).

(a) Underapproximate the program by blocking  $C_1$  and  $C_2$ .

a new underapproximation by blocking  $C_1, C_3$  and  $C_4$ .

Fig. 4: How UnderWidenSI works

Essentially, blocking callsites creates underapproximations of the set of feasible program paths. Such underapproximated VCs can be constructed by asserting additional *blocking* clauses corresponding to the control-flow variables of the open callsites. These blocks disallow reachability to certain program states. For example, in Figure 4a, we construct an underapproximated model of the program by blocking the open callsites  $C_1$  and  $C_2$ . The inner green oval depicts the program states that are reachable in the underapproximated model, whereas the outer *gray* regions demonstrate the states that are unreachable due to the blocks on  $C_1$  and  $C_2$ .

If the verification query on this model (conjunction of the underapproximated model and the negation of the property) returns SAT, it implies that an error state in indeed reachable. On the other hand, if the query returns UNSAT (as shown in Figure 4a), we need to *widen* the model to procure additional reachable executions. We guide this widening operation by extracting the reason for this unsatisfiability from a minimal unsat core  $^{5}$  of the query, that returns the set of block clauses; the callsites corresponding to these blocking clauses constitutes a reason of why the current underapproximate model is not able to reach any of the error states. Hence, we widen the model by unblocking exactly these callsites

<sup>&</sup>lt;sup>5</sup> Although there may exist multiple minimal unsat cores, we found via some preliminary experiments that the choice of the unsat core does not have a significant impact on the overall runtime of our algorithm (on an average).

Fig. 5: How OverRefSI works

leading to a wider model (see Figure 4b). The widening by inlining  $C_2$  causes a stratified inlining step, and hence may open up new callsites, say  $C_3$  and  $C_4$ .

We proceed in the same manner by blocking these open callsites and repeat the query. Finally, (in Figure 4c) we construct an underapproximated model that still does not intersect with the error states. However, in this case, the unsat core does not contain any blocked clause, as none of the currently blocked callsites would have allowed widening in the direction of the error states.

The unsat core provides a *direction* for widening towards the error states. This also allows us to declare that the program is *safe* without requiring to widen the model to encompass the set of all reachable program states—if the verification query is UNSAT and the unsat core does not contain any blocked clause, then this forms a sufficient condition to declare the program *safe*.

Figure 4d shows how our algorithm proceeds for a faulty program: it incrementally widens the model in the direction of the error states till an error state R is reached. At this point, the *UnderWidenSI* algorithm declares the program as *unsafe*.

Let us now contrast the UnderWidenSI strategy with the OverRefSI strategy, popularly known as counterexample-guided abstraction refinement (CEGAR), which currently drives the SI algorithm in CORRAL. OverRefSI starts off with an overapproximated model of the program: the pVC of the entry procedure with all callsites replaced by non-deterministic updates to its set of modified variables. For example, in Figure 5a, OverRefSI constructs an abstract program/overapproximated model  $M_1$  of the program by overapproximating the open callsites. If the resulting verification condition is SAT, it examines the generated counterexample to check if it spurious. If the counterexample is found to be a true bug, it declares the program unsafe. If the counterexample is spurious, the model is refined to eliminate this spurious counterexample. For example, in Figure 5a, we find that there exists an error state/counterexample P within  $M_1$ , where the property can be violated. Hence, OverRefSI refines  $M_1$  in Figure 5a by inlining the overapproximated callsites through which P is reachable. The refinement is done to rule out P as a counterexample, i.e., P becomes unreachable after

refinement. We observe in Figure 5a, that after the first round of refinement, P is no longer reachable in the overapproximated  $M_2$ , however, we can still find another counterexample Q. Hence, the abstraction  $M_2$  is refined again. The program is declared *safe* when the model cannot reach any error state. Note that the algorithm can prove the safety of the program without requiring to precisely capture the exact set of reachable program state.

OverRefSI and UnderWidenSI are complementary: while OverRefSI maintains an overapproximated model and refines the model (shrinking the set of reachable states), UnderWidenSI maintains an underapproximated model and widens the model (expanding the set of reachable states) incrementally. In terms of the algorithmic details, the OverRefSI algorithm in CORRAL uses the models (the counterexamples) to drive refinements, whereas our UnderWidenSI algorithm uses the proof (the unsat core) to guide the widenings.

#### 4 Algorithms

#### 4.1 Underapproximation Widening Guided Stratified Inlining (UnderWidenSI)

The UNDERWIDENSTEP routine in Algorithm 3 demonstrates how the Under-WidenSI strategy works in each verification step. It takes as input a procedure P, a set of open callsites C and an SMT solver S. The UNDERWIDENSTEP routine is called by the SI algorithm (instead of OVERREFSTEP in Line 4) iteratively in order to verify the safety of P.

In the beginning, we construct an underapproximated pVC of the input procedure P by blocking all calls through the open callsites in C (Line 4). Next, we fire an underapproximation query (Line 5). If the query returns SAT, then we return the verdict UNSAFE with the counterexample trace (Line 6). Otherwise, we get the minimal unsatisfiable core uc and extract all the blocked callsites which appear on uc in  $\mu$  (Line 8).

If  $\mu$  does not contain any blocked callsites, we deduce that P is SAFE. The proof of the safety of P is captured by uc. Hence, we return the verdict that P is SAFE. Otherwise, each of the callsites in  $\mu$  are then inlined (Line 15) which constructs a refinement of P. The inlined callsites are then removed from the list of open callsites C and new callsites that opened up due to the inlinings are added to C (Line 16).

When the algorithm is unable to arrive at a decision regarding the safety of P, it returns a verdict of NODECISION along with the list of inlined callsites  $\mu$  and the new list of open callsites C (Line 13).

**Example.** We demonstrate the working of *UnderWidenSI* to verify the pVC of main of Figure 1 in Table 2. Initially, we assert the pVC of main and add [main, (L1, foo)] and [main, (L2, bar)] to the list of open callsites in step 0. Replacing each of the open callsites with (*assume false*) statement, i.e., blocking them, constructs an underapproximation of the program. If an SMT solver query

Proof-guided Underapproximation Widening for Bounded Model Checking 13

Algorithm 3: UNDERWIDENSTEP(P, C, S)

**Input:** procedure P, set of callsites C, SMT solver S**Output:** SAFE, UNSAFE(*trace*), NODECISION( $\mu$ , C) 1 // Underapproximate check 2 S.Push() **3** forall  $c \in C$  do 4 |  $S.Assert(\neg ControlVariable(c))$ 5 if S.Check() == SAT then **return** UNSAFE( $\mathcal{S}$ .Model()) 6 7 else  $\mu \leftarrow \text{BlockedCallsites}(\mathcal{S}.\text{UnsatCore}())$ 8 9  $\mathcal{S}$ .Pop() 10 if  $\mu == \emptyset$  then return SAFE 11 12 else  $C' \leftarrow \emptyset$ 13 forall  $c \in \mu$  do  $\mathbf{14}$  $C' \leftarrow \text{INLINE}(\mathbf{P}, c)$ 15 $C \leftarrow (C - \mu) \cup C'$ 16 return NoDecision( $\mu, C$ )  $\mathbf{17}$ 

on this underapproximation returns SAT, then the program is surely UNSAFE as the satisfiable model can only represent an execution trace that goes through inlined callsites. In that case, we can return the verdict UNSAFE along with an error trace constructed from the model. On the other hand, if the underapproximation check returns UNSAT, then we cannot return a verdict on the safety of the program immediately.

Following this, in step 1 (see Table 2), we push a new frame on the solver and assert  $(\neg blk_{L1} \land \neg blk_{L2})$  to block executions through the callsites of **foo** and **bar** respectively to construct the underapproximated pVC of **main**. We query the solver with these constraints. Figure 1 shows that if we block executions through basic blocks L1 and L2, the program cannot terminate, i.e., the *return* statement in L3 is not reachable. Hence, the solver returns UNSAT. The reason for the unsatisfiability is blocking executions through both L1 and L2.

To widen the underapproximated model of the program so that we may reach L3, we need to remove the block on at least one of them and inline the respective callsite. The unsat core, in this case, contains the callsite of varbar in basic block L2. Therefore, we pop the earlier solver frame containing blocked clauses and assert  $(blk_{L2} \implies pVC(bar))$  in the solver. Inlining **bar**, opens up the callsites [main, (L2, bar), (L12, bar1)] and [main, (L2, bar), (L13, bar2)].

Next, in step 2, we again construct the underapproximated pVC of main by blocking executions through the callsites of foo, bar1 and bar2. The solver

Step	Action	Open Callsites
0	Assert pVC(main)	[main, (L1,foo)]
		[main, (L2,bar)]
1	Underapprox check: UNSAT	
	Assert $pVC(bar)$	[main, (L1, foo)],
		[main, (L2,bar), (L12, bar1)]
		[main, (L2,bar), (L13, bar2)]
2	Underapprox check: UNSAT	
	Assert $pVC(foo)$	[main, (L1,foo), (L6, foo1)]
	Assert $pVC(bar1)$	[main, (L1,foo), (L7, foo2)]
	Assert $pVC(bar2)$	
3	Underapprox check: UNSAT	
	Assert pVC(foo1)	
	Assert $pVC(foo2)$	
4	Underapprox check: UNSAT	
	Return SAFE	

Table 2: Execution of UnderWidenSI on the program of Fig. 1

query returns UNSAT with uc containing the callsites of foo, bar1 and bar2 which are inlined.

In step 3, the callsites of fool and foo2 are now open. Blocking both of these callsites and making an underapproximation check returns UNSAT with uc containing the callsites of fool and foo2. These callsites are now inlined.

In step 4, the underapproximation query returns UNSAT and uc contains no blocked callsites. This points to the fact that *uc* contains only inlined callsites, i.e., starting from step 0 if we only inline the callsites in uc and leave the remaining callsites overapproximated, we will still get an UNSAT. Therefore, uc is the proof of the safety of the program and we return the verdict that the pVC of main is safe.

Note that when the underapproximation query returns SAT, then the counterexample trace is constructed on the underapproximated program, i.e., the trace may contain only blocked and inlined callsites. The underapproximated program represents a subset of the paths in the original program, therefore, any counterexample trace present in the underapproximated program is sure to be present in the original program as well. Therefore, if the underapproximated program is unsafe, the original program is unsafe as well.

We have implemented the UnderWidenSI algorithm in LEGION. We compare the performance of the UnderWidenSI algorithm in LEGION against that of CORRAL which uses *OverRefSI*.

#### 4.2Portfolio Technique

The complementary behavior of the *OverRefSI* and the *UnderWidenSI* algorithms motivate us to design a portfolio approach for verifying a program. The portfolio strategy incorporates both the OverRefSI algorithm used by CORRAL

15

and the UnderWidenSI algorithm implemented in LEGION. We refer to the portfolio verifier as LEGION<sup>+</sup>. For each program, LEGION<sup>+</sup> runs both CORRAL and LEGION in parallel. LEGION<sup>+</sup> terminates verification as soon as one of the algorithms finishes verification and reports the outcome. We discuss the performance of LEGION<sup>+</sup> against that of CORRAL and LEGION in Section 5.

### 5 Experimental Results

We have built a tool, LEGION, that implements our UnderWidenSI algorithm. To compare against OverRefSI, we use CORRAL [26], a state-of-the-art verifier used at Microsoft [24]. We also build a portfolio solver, LEGION<sup>+</sup>, that runs both CORRAL and LEGION in parallel. Whenever one of the tools finish verification, LEGION<sup>+</sup> terminates the algorithms and reports the outcome.

We compare the performance of CORRAL against LEGION and LEGION<sup>+</sup> on a suite of Windows and Linux device driver benchmarks. The Windows device driver benchmarks are obtained by running Static Driver Verifier (SDV) [4] on real windows device drivers that exercise all features of the C language such as arrays, heaps, pointers, loops, recursion etc. SDV compiles these drivers into a suite of BOOGIE [8] programs, each of which is a device driver paired with property (compilation is detailed in [24]). Note that, although the suite of Windows device drivers compiled into BOOGIE programs are available as SDV benchmarks [31], the actual C programs are internal to Microsoft.

Along with this, we also use a set of Linux device drivers that are available as C programs as part of the SVCOMP benchmarks suite [7]. We used SMACK [36] to compile the Linux device drivers into BOOGIE programs. Overall, we elect to use a total of 727 hard programs, on which CORRAL took more than 200 seconds to verify or times out, from the SDV and SVCOMP benchmarks to run our experiments. We set the timeout for each verification task to 2 hours for both CORRAL and LEGION. For all verification tasks, We use an unrolling length of 3 as advised in the benchmarks [31] and used in other works [11].

As LEGION<sup>+</sup> uses twice the computational resources compared to CORRAL and LEGION, we halve its time budget to 1 hour to make a fair comparison. We also report the performance of LEGION<sup>+</sup> with a 2 hour time budget (it can be seen as the *virtual best* of CORRAL and LEGION).

The experiments were performed on a machine with AMD EPYC 7452 processor (48 cores) and 384 GB of RAM. Both CORRAL and LEGION uses Z3 [15] as the underlying SMT solver. We have used the default setting of a fixed random seed for Z3 for all our experiments after verifying the fact that the choice of random seed does not have any significant impact on our results.

#### 5.1 Corral Versus Legion

Figure 6 depicts the number of solved instances within the time budget by COR-RAL and LEGION. In Figure 6, a point (x, y) denotes the number of instances x, each of which was solved within time y. As we can observe, CORRAL is able to

16 Chatterjee et al.

Fig. 6: Number of instances solved within time (in hours) for CORRAL vs LEGION vs LEGION<sup>+</sup>.

Verifier	Solved Instances	Total Time Taken
Corral	262	109 hours
LEGION	351	112 hours
$\operatorname{Legion}^+$	369	71 hours

Table 3: Total time taken by each verifier to solve instances

solve 262 out of 727 instances (36%) with a time budget of 2 hours per instance, whereas LEGION solves 351 instances (48%) with the same time budget. Both of them fail to solve 330 instances (45%). Out of the 397 instances (55%) that are solved by either CORRAL or LEGION, 46 instances (12%) are solved exclusively by CORRAL, whereas 135 instances (34%) are solved exclusively by LEGION.

The scatter plot of verification times across LEGION and CORRAL is shown in Figure 7. The spread in the scatter plots demonstrate that these two tools complement each other—the benchmarks on which CORRAL struggles are sometimes handled well by LEGION, and vice-versa. Picking the best of two verifiers solves a total of 397 out of 727 instances (55%). This motivated the design of LEGION<sup>+</sup>.

#### 5.2 Performance of Legion<sup>+</sup>

As LEGION<sup>+</sup> utilizes parallelism, in order to make a fair comparison we halve the time budget for LEGION<sup>+</sup> on each verification instance to 1 hour. This means that LEGION<sup>+</sup> runs both the tools CORRAL and LEGION in parallel but with a time budget of 1 hour each.

Figure 6 shows that the portfolio verifier LEGION<sup>+</sup> solves 369 out of 727 instances (51%) with a 1 hour time budget, whereas CORRAL solves only 262

Fig. 7: Scatter Plot of Verification time of CORRAL vs LEGION.

instances (36%) with a total time budget of 2 hours. There are only 14 instances that CORRAL solves but LEGION<sup>+</sup> is unable to solve. Similarly, there are only 17 instances that LEGION solves but LEGION<sup>+</sup> is unable to solve.

With a 2 hour timeout,  $\text{LEGION}^+$  solves 397 instances in total (55%). This is essentially the *virtual best* of CORRAL and LEGION with a 2 hour timeout.

Figure 8 shows the total time taken (in hours) by CORRAL, LEGION and LEGION<sup>+</sup> to verify the instances that were solved by all three of them (total 213 instances). LEGION<sup>+</sup> is  $1.9 \times$  faster than LEGION and  $2.9 \times$  faster than CORRAL.

Across the benchmarks that each of the tools solve individually, CORRAL takes 109 hours to solve 262 benchmarks, LEGION takes 112 hours to solve 351 benchmarks, whereas LEGION<sup>+</sup> solves 369 benchmarks within only 71 hours (see Table 3).

Note that the benchmarks used in our study are those on which CORRAL took greater than 200 seconds. On the rest of the benchmarks, clearly LEGION<sup>+</sup> will perform at least as well as CORRAL. We chose to leave them out to ensure that the experiments run in a reasonable time: there were roughly 14000 of these easy cases. It allowed us to focus on benchmarks where speedup was important.

#### 6 Related Work

The high-level idea of using proof-guided abstractions has been long known [30,3]. Proofs of unsatisfiability have been used to derive abstractions for unbounded model checking in the context of microprocessor verification [30]. Amla et al. have also demonstrated that counterexample based abstraction is complementary to proof based abstraction and they can be combined in a judicious manner to reap the benefits of both the techniques for hardware verification tasks [3]. However, program verification has mostly been dominated by

Fig. 8: Cumulative time taken (in hours) to verify 213 instances that were solved by all three verifiers.

counterexample-guided abstraction refinement (CEGAR) based strategies. Of the few proposals that use proof-guided underapproximation widening strategies, most of them focus on verification of multi-threaded programs [18,35]. These techniques perform underapproximation on the number of thread interleavings allowed, while eagerly inlining all procedures. One technique [18] constrains the number of interleavings to certain bounds, while the other [35] uses dynamically inferred invariants for constructing (potential) underapproximations on interleavings. Note that, these techniques are orthogonal to our approach. Eager inlining is not feasible for our benchmarks, which is precisely the problem that we address. Our proposal shows that proof-guided widening strategies can be effectively employed for verifying large sequential programs. Proof of unsatisfiability from underapproximated models have also been utilized to narrow down the search space for overapproximation refinement in order to decide finite precision bit vector arithmetic with arbitrary bit vector operations [9]. The underapproximation is done on the bit vector variables of a propositional logic formula where some of the bit vector variables are encoded with fewer boolean variables than their width.

Other than using proofs to guide widening heuristics, proof artifacts, like interpolants, have been used to construct annotations [27,28,29,1,2] that can be useful in constraining future search. Such techniques are orthogonal to underapproximation widening based techniques. However, they can be useful for LEGION and we plan to investigate them in the future.

Underapproximation widening has also been used in program synthesis [37,40,39]. Instead of unleashing the search for the program on the whole search space, such techniques search for the desired program in an underapproximated search space. While prior approaches [37] used a pre-defined widening sequence, later approaches [40,39] use proofs of unsatisfiability to guide the widening sequence. Similar techniques have also been used in the synthesis of boolean functions [16,17]. Manthan [16,17] constructs an initial guess of the boolean function by sampling the specification and constructing a decision-tree classifier from the resulting data. It, then, uses a proof-guided technique to "repair" the learnt model into a desired function.

There have also been applications of the maximal satisfiable set (MAXSAT) on an unsatisfiable formula for program debugging. BugAssist [19] attempts to infer the set of suspicious locations using a MAXSAT formulation over an failing program trace and the specifications. Bavishi et al. [6] extend the formulation to provide a ranking over the suspicious locations such that the locations higher up in the rankings are less likely to cause regressions.

Another line of work is to use fuzzers to sample concrete instances and gradually build approximations of program behavior for the purpose of deductive verification [22] and symbolic execution [34]. However, such approaches use test instances and do not apply a proof-guided strategy.

LEGION is inspired by many of the above algorithms and, there is potential of incorporating more of these ideas in LEGION in the future.

### 7 Conclusion

Bounded model checking approaches for program verification predominantly focuses on CEGAR based strategies. In this work, we propose a proof-guided underapproximation widening strategy which behaves in a complementary manner to the CEGAR technique. The complementary nature allows us to build a portfolio strategy that takes advantage of both proof-guided underapproximation widening and CEGAR to deliver a significant speed up in verification time over both.

Our current approach only looks at the predicates corresponding to the callsites to figure out which are most relevant to the proof of unsatisfiability of the underapproximated model. In the future, we aim to extract additional information from the unsat core which would allow us to explore more involved widening strategies. Furthermore, combining the underapproximation techniques that work on the domain of thread interleavings to deal with a large space of sequential behaviors (via lots of procedures) and concurrent behaviors (via lots of interleavings) would be another interesting direction to explore. We also believe that underapproximation widening may yield improvement performance on our distributed bounded model checker, HYDRA [11,12]. Another interesting direction that we want to pursue is on combining bounded model checking algorithms (both overapproximation refinement and underapproximation widening) with dynamic analysis [5,38,13] and statistical testing [32,10] based approaches.

Acknowledgements. We wish to express our gratitude towards *Microsoft Azure* and *Google Cloud Platform* for providing us with computational resources for the experiments. We are also indebted to the PRAISE group of CSE department, IIT Kanpur and the anonymous reviewers for their helpful suggestions.
